54 A method and apparatus for continuously separating solids and liquids in a solids-liquid mixture.

57 A separation zone (118) for separating solids and liquids from a solids-liquid mixture is provided in which the mixture is subjected to centrifugal force under low shear forces and low turbulence. In the separation zone (118), the flow rate is maintained to be less than the terminal settling velocity of the solids in the mixture. The mixture is introduced into the separation zone (118) from a zone (120) of higher turbulence and higher flow rate than those of the separation zone (118), a minor part of the mixture in the other zone (120) being removed to the separation zone (118). The major part of the mixture is removed from the other zone (120) and discharged through a port (132) and returned to the mixture source in such a manner as to aerate the returned mixture. The separated solids are returned to the mixture source with the major part of the mixture. The separated solids and liquid are removed from the apparatus continuously. The invention is particularly useful in obtaining a highly clarified centrate from sewage sludge.

ACTORUM AG

A METHOD AND APPARATUS FOR CONTINUOUSLY
SEPARATING SOLIDS AND LIQUIDS
IN A SOLIDS-LIQUID MIXTURE

The invention relates to separation of solids and liquids in a solids-liquid mixture and more particularly to separation of solids and liquids in a sewage sludge mixture. The separation of solids and liquids may also involve aerating the mixture.

With respect to sewage sludge systems, existing continuous flow centrifuges are designed to thicken waste biological sludges. These centrifuges operate in a mode which results in fragmentation of the delicate biological sludges through shearing action in the aqueous phase. The result is a very turbid centrate containing relatively high solids concentration. As far as the applicant is aware, there are no centrifuges designed to provide highly clarified centrates while maintaining uninterrupted flow of both solid and liquid phases; particularly there are no centrifuges designed to provide highly clarified, high quality effluents by continuously separating sludges from the mixed liquor of an activated sludge system.

The applicant is also not aware of centrifugal apparatus or processes which provide for continuous separation of solids and liquids in a solids-liquid mixture and for aeration of the mixture in conjunction with separation.

According to one aspect of the invention, there is provided a method of separating solids and liquids in a solids-liquid mixture comprising the steps of introducing mixture to be separated into a first chamber, removing a minor part of the mixture into a second rotating chamber having a mass flow and turbulence which are substantially less than those in the first chamber, separating the mixture in the second chamber into solids and liquids and removing the separated solids and liquids from the second rotating chamber.

According to another aspect of the invention, there is provided apparatus for continuously separating solids and liquids in a solids-liquid mixture and continuously removing the separated solids and liquids from the apparatus comprising:-

- 5 an upstream chamber;
- means for introducing influent mixture into the upstream chamber;
- a downstream chamber spaced from the upstream chamber and disposed so as to be rotatable about an axis of rotation, and structured so as to separate therein solids and liquid in a solids-liquid mixture present in the downstream chamber upon rotation thereof about the axis;
- means for separating a minor part from the mixture in the upstream chamber and introducing said minor part into the downstream chamber;
- 15 means for removing separated liquid from the downstream chamber; and
- means for removing separated solids from the downstream chamber.
- 20 Aerating the solids-liquid mixture may occur in conjunction with separation. The separation may be of biological solids from liquids in a sewage sludge mixture or other biological system. The invention may obtain a highly clarified effluent from the mixed liquor of an activated sludge system or other biological process system. Biological sludges or other solids may be retained in a system while aerating these solids as a solids-liquid mixture and while discharging a highly clarified or partially clarified effluent as desired. The biological or other reactive sludges may be retained in a reactor vessel while permitting addition of and/or removal of soluble and/or solid materials at will on a continuous uninterrupted flow basis. Furthermore, the biological and/or other reactive sludges may be retained in a reactor vessel while adding or removing liquid or solid materials from the vessel and aerating or mixing the reactor contents with a gaseous reactant.
- 30 Shear forces can be eliminated or minimized within a
- 35

solids-liquid or a sludge-water separation or solids settling zone, while simultaneously providing a means for removing separated solids or sludges from the solids or sludge settling zone. Shear forces are reduced in the settling zone by means such as baffling, for example, which prevent circumferential slippage of the liquid within the settling zone. The baffling may extend transversely to the axis of rotation, preferably radially, or the baffling may extend axially, or both transversely and axially. Prevention of liquid shear or slippage in this zone permits a highly clarified centrate to be obtained.

Preferably the major part of the mixture is removed from the rotating upstream chamber and returned to the source of the solids and liquid mixture in a manner which results in aeration of the mixture.

The mass flow in the second chamber is preferably maintained substantially less than the mass flow in the first chamber and the mass flow in the second chamber is preferably maintained below the terminal settling velocity of the solids in the mixture. Shear forces are maintained low in the second chamber while subjecting the mixture to the centrifugal force obtained by rotation.

In the disclosed embodiments, each chamber is defined by respective axially spaced upstream and downstream surfaces which extend outwardly with respect to the axis of rotation, and spaced surfaces extending between respective upstream and downstream surfaces and between the axis of rotation and each chamber periphery.

A means for separating each chamber into an upstream region and a downstream region is disclosed to comprise a member in the chamber which extends outwardly, preferably radially from at or adjacent to the axis of rotation to adjacent the periphery of the chamber.

The upstream and downstream chambers may comprise regions of a chamber connected in the apparatus for rotation about an axis of rotation. Preferably, the means separating the chamber into the upstream region and the downstream region comprises a baffle extending radially from at or adjacent to the axis of rotation of the

chamber to adjacent the peripheral region.

In the disclosed embodiments, the upstream and downstream chambers or regions are structured such that the flow turbulence in the upstream chamber or region is substantially higher than the flow turbulence in the downstream chamber or region. Using Reynolds numbers as an indication of flow turbulence, the downstream chamber or region has a Reynolds number which is substantially less than the Reynolds number in the upstream chamber or region. For example, the downstream chamber or region may have a Reynolds number less than 3000 while the upstream chamber or region may have a Reynolds number of 3000 to 200,000 or greater.

In the disclosed embodiments, the means for communicating the upstream and downstream chambers or regions are disposed so as to communicate the upstream and downstream chambers or regions at a first location spaced outwardly from the axis of rotation, the means for communicating being the peripheral region in the chamber between the chamber periphery and an outwardly-extending member.

Also, in the disclosed embodiments: the means for introducing influent mixture into the upstream chamber or region is disposed so that mixture is introduced into the upstream chamber or region at a second location inwardly of the first location; the means for introducing influent is communicated with the upstream region at or adjacent to the axis of rotation of the chamber; the first means for removing effluent from the upstream chamber or region is communicated with the upstream region at or adjacent to the peripheral region and is disposed so that effluent is removed from the upstream chamber or region outwardly of the second location; and the second means for removing effluent from the downstream chamber or region is disposed so that effluent is removed from the downstream chamber or region inwardly of the means for communicating the upstream and downstream chambers.

In accordance with a preferred embodiment, a plurality of circumferentially disposed chambers or regions are provided.

The invention is diagrammatically illustrated by way of example in the accompanying drawings, in which:-

Figure 1 is an axial section view of a single chamber separator apparatus according to one embodiment of the invention;

5 Figure 1A is an axial section view of a portion of the single chamber separator apparatus of Figure 1 illustrating an alternate connection for the pump which draws mixture into the apparatus;

Figure 2 is a perspective view partially in section of a multi-chamber separator apparatus according to the invention;

10 Figure 3 is a perspective view partially in section of the separator apparatus of Figure 2 depicting the fluid flow in the apparatus; and

/ Figure 4 is a perspective view partially in section of the separator apparatus of Figure 2 depicting particle distribution and flow.

15 Referring to the drawings, a single chamber separator apparatus 10 (Figure 1) and a multi-chambered separator apparatus 100 (Figure 2) are illustrated.

The separator apparatus 10 in Figure 1 includes a single chamber 12 formed in a chamber housing 14. The chamber housing 14 is solid, except for the chamber 12 therein and passages 16, 18 and 20 communicating with the chamber 12. The chamber housing 14 with the chamber 12 disposed therein is connected in the apparatus 10 for rotation about an axis 22. The chamber 12 extends (in cross-section) radially in the chamber housing 14 from adjacent the axis of rotation 22 to adjacent the periphery 24 of the chamber housing. The chamber 12 is formed by an outwardly-extending (in cross-section) upstream surface 26, an outwardly-extending (in cross-section) downstream surface 28 and a generally axially-extending (in cross-section) peripheral surface 30. The chamber 12 is further defined by spaced surfaces 31 which extend axially between the upstream 26 and the downstream 28 surfaces and radially from adjacent the axis of rotation 22 to the peripheral surface 30. The passage 16 is an upflow effluent passage and is communicated with the chamber 12 adjacent the axis of rotation 22 through the downstream surface 28. The passage 18 is an influent passage and is communicated with the chamber

12 adjacent the axis of rotation 22 through the upstream surface 26. The passage 20 is a downflow effluent passage and is communicated with the chamber 12 adjacent the peripheral surface 30.

The chamber 12 is separated into an upstream region 32 and a downstream region 34 by a radially-extending (in cross-section) baffle 36. The baffle 36 extends radially from adjacent the axis of rotation 22 to adjacent the peripheral surface 30 and circumferentially between the surfaces 31. Between the extremity 38 of the baffle 36 and the peripheral surface 30 of the chamber 12 and between the upstream 26 and the downstream 28 surfaces of the chamber is formed a peripheral region 40. In order not to leave a dead space, peripheral corners 40A of both the upstream and downstream chambers may be filleted or the upstream and downstream surfaces may include sections having axially-extending components which extend towards the centre of the chamber peripheral surface 30. This is generally referenced by fillets 41 in Figure 1.

In addition to the chamber housing 14, the apparatus 10 includes an upstream section 42A, 42B and a downstream section 44, both sections extending axially (in cross-section) from the chamber housing 14. The sections 42A, 42B and 44 rotate with the chamber housing 14 about the axis 22, suitable means, for example bearing means, being provided, at position 46 and/or 47 for example, to support the apparatus and permit rotation thereof about the axis 22. In one embodiment, a rotating seal is provided at a position 49 and a pump 62 draws liquid through the upflow passage 16. In another embodiment (Figure 1A), a liquid seal is provided at a position 48 and a pump 63 draws the solids-liquid mixture into the passage 18. Conventional drive means, not shown, are provided to effect rotation of the apparatus 10.

In the embodiment shown in Figure 1, the passage 16 extends axially downstream along the axis of rotation 22 from the downstream region 34 of the chamber to an effluent port at a position 49 and is formed as the bore 50 of a hollow rotating shaft 52. The influent passage 18 extends axially upstream from the chamber 12 along the axis of rotation 22 through the sections 42A and 42B to a source or

reservoir of the solids-liquid mixture, and is formed as a central, axially-extending bore 54 in the sections 42A, 42B. The downflow effluent passage 20 has a portion 20A extending radially inwardly in the housing 14 and a portion 20B extending axially from the 5 housing 14 in the upstream section 42A, and is formed as another axially extending bore radially offset from the axis 22 in the section 42A. The passage 20 terminates at ports 58 after passing through a liquid trap which prevents a siphon break in the passage 20. A sleeve 59 is rotatably mounted on the section 42A by means of 10 a slip-fit, for example, and can be manually rotated relative to the section 42A to act as a control valve for the rate of discharge from the ports 58. A passage 61 in the sleeve 59 is circumferential and provides passage of discharge from the two diametrically opposed ports 58 to maintain balance.

15 In operation, the influent passage 18 is communicated with a source or supply of a solids-liquid mixture 60, i.e. the central bore 54 of the upstream section 42 is disposed in the solids-liquid mixture 60. Additionally, the effluent ports 58 are disposed in the mixture at least initially for priming. The pump 62 is communicated 20 with the downstream bore 50 of the shaft 52 with the rotating seal at the position 49 between the pump and the shaft. The chamber housing and the upstream and downstream sections of the apparatus are rotated and the mixture 60 is drawn into the central bore 54 of the downstream section 42A, 42B initially by means of the pump 62. 25 Mixture is also drawn into the effluent ports 58. Pumping by the pump 62 eventually causes the mixture to progress in the passages 18 and 20 and enter the upstream, peripheral and downstream regions of the chamber and thereafter enter the downstream passage 16. Air is thus displaced by the mixture in the passages 16, 18 and 20 and 30 in the chamber 12 to prime the apparatus. Rotation of the apparatus causes the mixture in the chamber to move centrifugally outwardly and provides a built-in pumping action which draws mixture into the upstream region 32 of the chamber via the passage 54.

35 Alternatively the pump 63 is connected as shown in Figure 1A through a rotating seal to the bore 54 of the downstream section 42B

to draw mixture into the apparatus.

Once the apparatus is primed, the ports 58 may be raised from the solids-liquid mixture and centrifugal force will cause the mixture in the upstream region 32 of the chamber 12 to move radially outwardly with a part thereof eventually being discharged from the ports 58 through the passage 20. The pumps and pumping action are selected so that a major part of the mixture entering the passage 54 is removed from the upstream region 32 through the passage 20 and a minor part is removed to the downstream region. More specifically, 5 a major part 60A of the solids-liquid mixture in the upstream region 32 is withdrawn therefrom through the downflow effluent passage 20, while a minor part 60B progresses upstream through the peripheral region 40 into the downstream region 34 of the chamber 12. The rate of flow of the minor part of the mixture 60B is determined by the 10 pump 62 and the rate of flow of the major part of the mixture 60A is determined by the pumping action of the rotating apparatus or by the pump 63. Thus, the pump 62 and the pump 63 or the rotating 15 action of the apparatus are primarily responsible for the relative division of the mixture in the region 32.

The upstream region 32 is intended to be a turbulent zone in which little or no separation takes place and the downstream region 34 is intended to be quiescent zone in which turbulence is substantially reduced as compared to that in the upstream region 32. The baffle 36 isolates the quiescent zone from the turbulent zone 20 so that the minor part 60B of the mixture 60 drawn into the downstream region 34 is not subjected to high shear forces. Thus, quiescent conditions are established in the downstream region 34 25 so that the solids are subjected to high centrifugal forces, but low shear forces, and move radially outwardly, the liquid moving radially inwardly. The separated solids flow axially upstream as downflow through the peripheral region 40 and are entrained in the major part 30 60A of the mixture moving through the downflow effluent passage 20.

The turbulence in the upstream region 32, the downflow effluent passage 20 and the peripheral region 40 is dependent upon 35 the flow rates as discussed. For a given mass flow of mixture 60,

the turbulence increases in the region 32 as flow approaches the peripheral surface 30. The increasing turbulence, as region 32 flow approaches the peripheral region 40, ensures suspension and flow of solids in these regions. The radial cross-sectional area 5 of the peripheral region 40 is determined by the distance that the baffle 36 extends radially from the axis of rotation. The cross-sectional area of the region 40 regulates the turbulence in the region 34 adjacent to the peripheral region 40. The regulated turbulence in the region 34 adjacent the peripheral region 40 coupled 10 with the relatively low flow rate of the minor part 60B of the mixture in the regions 40 and 34 serve to rapidly decrease turbulence and relative velocity of flow in these regions. Solid particles, no longer being suspended by flow or turbulence, are centrifugally thrown toward the downstream peripheral walls 30 and 41 and into 15 the peripheral region 40 where turbulence is higher and they can be re-suspended with the major portion 60A of the mixture at the entrance 20C to the downflow effluent passage 20.

The circumferential width of the chamber 12 is limited by the spacing between the surfaces 31. The spacing is selected to 20 provide low or limited shear forces between the baffle 36 and the mixture and between the chamber surfaces and the mixture. Thus, circumferential slippage is reduced or eliminated between the mixture and the surfaces in the quiescent downstream region.

The major part 60A of the influent mixture 60 in the upstream chamber 32 is removed therefrom as described and progresses 25 as downflow through the bore 56 to be discharged through the effluent ports 58. The minor part 60B of the mixture 60 progresses into the downstream region 34 where separation of the solids and liquid in the mixture takes place, the separated solids being again entrained 30 in the major part 60A of the mixture and removed from the apparatus as downflow through the ports 58 and the separated liquid being removed as upflow through the downstream passage 16.

By way of example, the fluid motion in the chamber 12 may be described by means of Reynolds numbers associated with the 35 different regions of the chamber. Noting that turbulent flow occurs

at Reynolds numbers above about 3,000, the Reynolds number in the upstream region turbulent zone is from about 3,000 to about 200,000, or greater. The Reynolds number is reduced in the peripheral region 40 and in the downstream region quiescent zone is less than about 5 3,000. In addition the flow velocities in the upstream region 32 and in the radially inwardly projecting downflow effluent passage 20 must be such that the terminal settling velocity of the solids particles suspended in the mixture 60 are exceeded. The flow velocities in the downstream region 34 and in the portions of the 10 peripheral region 40 which are adjacent the downstream region 34, must be less than the terminal settling velocities of the solid particles in the mixture 60. The separated liquid upflow is removed as a highly clarified effluent by the pump 62 while the separated solids and the major part of the mixture are returned to the reservoir. It is to be noted, however, that the centrifugal action in 15 the rotating chamber 12 assists in pumping the major part 60A of the mixture in that once primed by the pump 62 with the ports 58 submerged, the device may be elevated so that liquid discharging from the ports 58 is so released above the surface of mixture 60 and causes by passage through air and by impact with the mixture 60, 20 the aeration of the mixture 60. Alternatively to the submergence of the ports 58 during priming, the pump 63 can be used to prime the device 10 after which centrifugal pumping action of the device will maintain flow in the upstream region. It is possible by the 25 use of the pump 63 and proper restriction of flow at the ports 58, to eliminate the need for the pump 62.

In use for separating sewage sludge, mixture enters the quiescent sludge settling zone 34 flowing at a rate determined by the pump 62. By keeping this flow rate low relative to the cross-sectional area of the sludge settling zone 34, it is possible to 30 establish quiescent conditions within this zone such that the sludge is exposed to high centrifugal forces but very low shear energy. As a result, the sludge settles rapidly toward the periphery or outer wall of the region 34. Turbulence in the turbulent flow zone 32 35 carries over into the peripheral region 40 and the entrance to the

quiescent zone 34 and causes the separated sludges to be entrained in the mixed liquor flowing through the turbulent flow zone. Thus, the sludge settling zone is kept reasonably quiescent while separated sludges are continuously removed from that zone.

5 The apparatus 10 thus provides for separation of liquids from the mixture and removal thereof from the apparatus on a continuous basis and for separation of solids from the mixture and removal thereof from the apparatus on a continuous basis, i.e. the apparatus need not be stopped and the process discontinued to 10 remove separated liquids and/or separated solids.

As described above, the effluent ports 58 are initially submerged to prime the apparatus. Thereafter, the effluent ports may be removed from the mixture and be raised above the mixture level. This is done so that a vertical distance is provided between the 15 effluent ports 58 and the mixture, thus allowing the downflow effluent discharged to fall through air in a trajectory established by centrifugal force and gravity before reaching the mixture. The downflow effluent also impacts the surfaces of the containing vessel or the mixture 60 causing entrainment of air in the mixture. Thus, 20 the downflow effluent which includes a major part of the mixture introduced into the apparatus is aerated in conjunction with separation and through impact aerates the mixture as a whole on a continuous basis.

Referring now to Figure 2, a multi-chambered separator apparatus 100 is illustrated. The apparatus 100 includes a chamber housing 104 which rotates about the axis 22 and is partitioned into chambers 102. The chambers 102 in the housing 104 extend generally radially from or adjacent to the axis of rotation 22 as described for the single chamber of apparatus 10. Each chamber is circumferentially juxtaposed in the housing 104 and is formed by a respective upstream baffle 106, a respective downstream baffle 108 and one or more peripheral surfaces 110. Adjacent chambers are separated by axially-extending circumferentially-spaced baffles 111, i.e. the baffles 111 partition the housing 104 into the chambers 102. Although each of the chambers 102 is illustrated to be identically 25 30 35

structured, the chambers need not be identical and may, for example, have different dimensions. Influent is introduced into the chambers 102 by an influent passage referenced generally by 112 and downflow effluent is removed from the chambers 102 by a downflow effluent passage referenced generally by 114. An upflow effluent passage referenced generally by 116 is also communicated with the chambers 102.

A baffle 118 radially extending from an adjacent to the axis of rotation 22 to adjacent the peripheral surfaces 110 separates the chamber 102 into an upstream region 120 and a downstream region 122. A peripheral region 124 is formed adjacent to the extremity 126 of the baffle 118 and the peripheral surfaces 110. The downflow effluent passage 114 is formed by the upstream baffle 106, a baffle 128 and another baffle 130 in the chamber housing 104. The downflow effluent passage 114 is sinuous, extending first radially inwardly, then making a U-turn around the baffle 128 and thereafter proceeding radially outwardly and terminating in a downflow effluent port 132. The general configuration of the downflow effluent port 132 will affect the efficiency of aeration and may provide horizontal (as shown) or vertical or angular (from about 30° to about 90° with the horizontal) discharge. The baffle 106 of the chamber 102 extends from the influent passage 112 radially outwardly to adjacent the chamber peripheral surfaces 110. The baffle 128 extends from the peripheral surface 110A to adjacent the influent passage 112.

The influent passage 112 is separated from the effluent passage 114 by an axially-extending section from which the baffles 106 and 130 extend, the passage 112 being communicated with the interior of the chamber 102 adjacent the baffle 106.

The peripheral region 124 is formed by the extremity 126 of the separating baffle 118 and the peripheral surfaces 110A and 110B. The surface 110A extends axially with respect to the axis 22 while the surface 110B extends inwardly toward the axis 22, the surfaces 110A and 110B preferably intersecting upstream of the axial location of the baffle 118. The surfaces 110A and 110B, however, may intersect at or downstream of the axial location of the baffle

118. Thus, the peripheral region 124 and the downflow effluent passage 114 are in communication along the surfaces 110A and 110B, the surface 110A forming part of the passage 114.

Each upstream region 120 of the chambers 102 is isolated
5 from adjacent chambers by means of the axially extending baffles 111 which also extend radially outwardly from the wall 134 to the peripheral surfaces 110A and 110B. In addition, the downflow effluent passage 114 is divided into a multiplicity of isolated sub-passages 114A, B by the baffles 111.

10 Each of the downstream regions 122 of the chamber 102 is formed by the separating baffle 118, the peripheral surface 110B, the downstream baffle 108, and the upper or downstream portion 111B of the circumferentially-spaced axially-extending baffles 111, the baffles 111 extending axially from the downflow effluent passage 114 to the downstream region 122. The lower or upstream portions 111A of the baffles 111 are disposed to separate adjacent ones of the sub-passages 114A, B and to isolate the adjacent upstream regions 120. The downstream or upper baffle portion 111B extends from the surface 110B radially inwardly to adjacent the downstream shaft 138 of the apparatus. The baffle 108 extends radially inwardly from the surface 110B to or adjacent to or adjacent to the inner peripheral extremity of the upper baffle portions 111B. Preferably the radius of the inner extremity of the baffle 108 is greater than the radius of the inner extremity of upper baffle portions of the baffle 20 portions 111B, and is configured as a V-notch weir. An annular region 140 is provided which is common to all of the downstream 25 regions 122.

The baffle 144, extends radially inwardly to and beyond the inner peripheral extremity of the upper baffle portions 111B and the 30 inner extremity of the baffle 108. The baffle 144 together with the baffle 108, the surface 110B and the upper baffle portion 111B form the upflow effluent passage 116. The upflow effluent passage 116 is sub-divided into a multiplicity of isolated passages 116A, B etc., by axially extending baffles 148. The baffles 108, 144 and 148 35 extend radially outwardly to form upflow effluent ports 146. The

axial baffles 148 between the baffles 108 and 144 may be curved appropriately to improve energy efficiencies of the overall device through kinetic energy recovery from the upflow effluent discharge. An annular upflow effluent collector 150 is disposed in communication with each of the effluent ports 146 to collect the effluent discharge therefrom. A single upflow effluent discharge port 152 is provided for the collector 150.

It is pointed out that the baffles 144, 108, 118, 106, 128 and 130 are of overall disc-like or annular configuration when considering the housing 104 as a whole.

A central opening 155 in the top surface 157 of the collector and a central opening 159 in the baffle 144 provide venting from the interior of the downstream chambers and permit access thereto for observation or to obtain samples. The surface 157 and the baffle 144 prevent the liquid being collected from splashing out of the apparatus 100. If the apparatus 100, however, is operated in an enclosure such as a tank having a cover, the surface 157 and the baffle 144 may be omitted, if desired. Also, if desired, the surface 157 and the baffle 144 may extend to the shaft 138 with holes being disposed in the surface 157 and in the baffle 144 for venting.

The influent passage 112 is formed co-axially with the axis of rotation 22 and its upstream end 153 is disposed in a reservoir of mixture to be separated. The housing 104 and all its contents, the downstream shaft 138 and the upstream influent passage 112 are rigidly connected for rotation as a unit. Conventional means, not shown, are provided for rotating the chamber housing and the upstream and downstream portions of the apparatus. The collector 150 remains stationary and means may be provided to seal the collector and the rotating chamber.

In operation, the apparatus 100 is rotated about the axis 22 and influent mixture is pumped into the passage 112. This may be accomplished by means of a separate pump or the passage 112 may be an inverted truncated cone as illustrated in Figure 2 which extends 35 into the mixture and is provided with axially-extending vanes 154

which also extend into the mixture in the reservoir. The rotating vanes in combination with the conical configuration of the passage 112 provide a pumping action and pump the mixture into the influent passage 112. The mixture proceeds downstream in the passage 112 and is introduced into the upstream region 120 of the chamber 102 adjacent the axis of rotation 22. As described above for the embodiment shown in Figure 1, the influent mixture in the upstream chamber 120 is divided into two parts, a major part proceeding into the downflow effluent passage 114 and a minor part proceeding into the peripheral region 124. The factors which determine the division are the pumping rate of the external pump or truncated conical pump, the relative displacement of the inner extremities of the radially-extending baffles 108 and 128 from the axis of rotation, the cross-sectional area of the peripheral region 124 as defined by the outer extremity of the radial baffle 118 and the surface 110B, the cross-sectional area of the downflow passage 114 and the cross-sectional area of the upstream region 120. The mixture is pumped up into the region 120 of the chamber 102 as the apparatus is rotated and fills the upstream region 120 and the downstream region 122, thus creating a flooded zone between the baffles 128 and 108. Apertures 160 are provided in the baffle 118 adjacent the shaft 138 to permit air between the baffle 118 and the flooded passage 112 to be removed. Means may be provided to regulate the size of the apertures or close the apertures to control the removal of air. As pumping progresses so that more mixture is introduced into the region 120 within the flooded zone, mixture spills over the inner extremity of the baffle 128 from which it is discharged through the port 132. Mixture also spills over the inner extremity of the baffle 108 into the passage 116 from which it is discharged through the port 146. Of course, as the apparatus 100 is rotated faster, more mixture will flow up in the passage 112 to increase the separating capacity of the apparatus. However, the maximum separating capacity is limited by the rate of flow in the downstream region 122 and the quality of separation desired. Separation of solids and liquids otherwise occurs generally as described for Figure 1, the separation being controlled

by flow rates and turbulence as described for Figure 1.

Referring now to Figure 3, the apparatus of Figure 2 is illustrated in which the flow of the mixture is shown. An upflow is provided in the influent passage 112 with the mixture being removed therefrom into the upstream region 120 of the chamber. The major part of the mixture in the region 120 is removed therefrom through the downflow effluent passage 114. The minor part of the mixture proceeds through the peripheral region 124 into the downstream region 122 and is separated into solids and liquids. The solids form part of the downflow and progress down through the peripheral region 124 into the passage 114 to be discharged from the apparatus with the major part of the mixture. The separated liquids move radially inwardly into the annular region 140 and are centrifuged therefrom into the effluent discharge ports 146. More specifically the minor part of the mixture entering the peripheral region proceeds into a quiescent zone in the region 122 and separation of solids and liquids in the minor part of the mixture takes place. The solids are centrifuged outwardly and form part of the effluent downflow, proceeding upstream in the peripheral region 124 to join the effluent downflow of the major part of the mixture. The major part of the mixture and the separated solids are discharged from the downflow effluent port 132. The separated liquids in the upstream region 122 move inwardly into the annular region 140 and then proceed outwardly into the effluent ports to be discharged into the collector 150. A highly clarified effluent is obtained from the discharge port 152.

The peripheral region 124 in the separator of Figure 2 is formed, as mentioned, adjacent the extremity 126 of the baffle 118 and the two surfaces, 110A and 110B. The surface 110A extends axially and forms part of the upstream region 120. This axially-extending surface creates a zone of high turbulence, by redirecting the major part of the mixture flow into the downflow effluent passage. The surface 110B extends at an angle inwardly from the axially-extending surface 110A and reduces turbulence as the surface progresses inwardly toward the radial plane and the extremity 126.

of the baffle 118 and beyond. Thus, the turbulence decreases as the peripheral region 124 extends downstream. Within the downstream region 122, turbulence is substantially eliminated by divergence of the surface 110B and the baffle 118 and the quiescent zone thereby provided. The centrifugal force and the low shear forces act to provide separation of the solids and liquids in the quiescent zone 122, and in the region of transition from the peripheral region 124 to the region 122. While extending the surface 110 inwardly is preferred, the surface 110 may extend axially from the surface 110A. In such a case, it is preferred that the corner formed by the surface 110B (axially-extending) and the baffle 108 be filleted to avoid a dead space.

Referring now to Figure 4, a portion of the apparatus 100 of Figure 2 is illustrated in which the solids distribution, solids flow and flow turbulence in the apparatus are depicted. The major part of the solids proceed with the liquid as a mixture as described for Figure 3, into the upstream region 120 and into the downflow effluent discharge passage 114. A minor part of the mixture proceeds into the peripheral region 124 where turbulence is reduced as the peripheral region progresses into the downstream region 122. The solids are separated in the downstream region adjacent the peripheral region 124 and returned through the peripheral region to the upstream region and hence to the downflow in the discharge passage 114.

As described for the apparatus 10, the baffles 111 are spaced to provide low shear forces and reduce slippage between the mixture and the rotating chamber surfaces.

As described for Figure 1, separation and removal of liquids is on a continuous basis and separation and removal of solids is also on a continuous basis.

In some applications, it is highly desirable to aerate the discharged solids and the major part of the solids-liquid mixture before returning the same to the mixture reservoir. Thus, the downflow effluent port 152 is advantageously spaced from the mixture level in the reservoir as described for the embodiment of Figure 1

and the discharged effluent must pass through a layer of air before being returned to the reservoir. Further, the impact of the re-turning discharged mixture on the surface of the bulk mixture entrains air bubbles in the bulk mixture and induces mixing of the
5 body of the mixture.

While the apparatus described above is useful in separating solids and liquids in many types of solids-liquid mixtures, the invention is particularly suited to separating solids and liquids in a solids-liquid sewage mixture and obtaining a highly clarified
10 effluent. Specifically, the invention is especially suited for use in activated sludge systems for biological waste water treatment. Advantageously, the invention prevents fragmentation of the delicate biological sludges since shear forces in the separating zone are held to a minimum. The invention can permit the bulk of the mixture
15 introduced into the separating apparatus to be aerated continuously during separation of solids and liquids, both separation and aeration being accomplished with one source of power. For the embodiment described in Figure 1, this device may be utilized to provide highly clarified effluent for analytical purposes.

20 Means other than baffles may be used to form the rotating chamber and the upstream and downstream regions. It is within the contemplation of the invention to utilize valving, for example, to communicate the upstream and downstream regions and to utilize valving to accomplish division of the mixture in the upstream region
25 into a major part which is removed from the chamber and a minor part which is supplied to the downstream region.

CLAIMS

1. Apparatus for continuously separating solids and liquids in a solids-liquid mixture and continuously removing the separated solids and liquids from the apparatus comprising:-
 - an upstream chamber;
 - means for introducing influent mixture into the upstream chamber;
 - a downstream chamber spaced from the upstream chamber and disposed so as to be rotatable about an axis of rotation, and structured so as to separate therein solids and liquid in a solids-liquid mixture present in the downstream chamber upon rotation thereof about the axis;
 - means for separating a minor part from the mixture in the upstream chamber and introducing said minor part into the downstream chamber;
 - means for removing separated liquid from the downstream chamber; and
 - means for removing separated solids from the downstream chamber.
2. Apparatus according to claim 1, including means for removing a major part of the mixture from the upstream chamber and discharging it as effluent.
3. Apparatus according to claim 1 or claim 2, wherein the upstream chamber is disposed so as to be rotatable about the axis.
4. Apparatus according to any one of claims 1 to 3, wherein said means for separating and introducing include means for communicating the upstream and downstream chambers.

5. Apparatus according to claim 4, wherein solids are removed from the downstream chamber through said communicating means.

6. Apparatus according to any one of claims 1 to 5, wherein said solids are mixed with the major part of said mixture in said means for removing a major part of said mixture.

7. Apparatus according to any one of claims 1 to 6, wherein each said chamber is defined by respective axially spaced upstream and downstream surfaces which extend outwardly with respect to the axis of rotation and by spaced surfaces extending between respective upstream and downstream surfaces and between the axis of rotation and each chamber periphery.

8. Apparatus according to any one of claims 1 to 7, wherein the upstream and downstream chambers are structured such that the flow turbulence in the upstream chamber is substantially higher than the flow turbulence in the downstream chamber.

9. Apparatus according to any one of claims 1 to 8, wherein the downstream chamber has a Reynolds number of less than 3000 while the Reynolds number in the upstream chamber is substantially greater.

10. Apparatus according to any one of claims 1 to 9, wherein the downstream chamber is structured to provide high centrifugal forces and low shear forces to mixture therein during rotation of the downstream chamber.

11. Apparatus according to any one of claims 1 to 10, wherein said means for introducing influent comprises means for removing mixture from a source of the mixture and a passage in communication with the upstream chamber which can be communicated with the source of the mixture.

12. Apparatus according to claim 11, wherein said means for introducing influent comprises a hollow generally conically-configured shaft, the larger end of which is in communication with the upstream chamber and the smaller end of which can be communicated with a source of mixture, the shaft having a plurality of generally axially-extending vanes disposed therein which act to pump mixture from the source and introduce it into the upstream chamber.

13. Apparatus according to any one of claims 1 to 13, wherein said means for removing separated liquid from the downstream chamber includes a passage in communication with the downstream chamber and pumping apparatus coupled to the passage to pump fluid from the downstream chamber.

14. Apparatus according to any one of claims 1 to 13, including outlet means in communication with said means for removing said major part of the mixture from the apparatus, the outlet means being spaced above a reservoir of the solids-liquid mixture from which mixture is drawn into the apparatus such that the separated solids and mixture can be aerated when discharged from the outlet means.

15. Apparatus according to claim 7, wherein a peripheral region is disposed at peripheral edges of the downstream surface of the upstream chamber and the upstream surface of the downstream chamber extending into the upstream and downstream chambers.

16. Apparatus according to any one of claims 1 to 15, wherein the upstream and downstream chambers are disposed in a generally cylindrical housing connected in the apparatus for rotation about the axis; a first disc-like baffle member is disposed on the axis and extends radially therefrom to adjacent the periphery of the housing, the first baffle member separates the housing into the upstream and downstream chambers, there being a peripheral region intermediate the first baffle member and the periphery of the housing; an upstream conduit extends coaxially with the axis into the

housing and in communication with the upstream region; a second annular baffle member is disposed on the axis and spaced upstream from the first baffle member, the second baffle member extending radially from the upstream conduit to adjacent the periphery of the housing and forming a turbulent region with the first baffle member; and a third annular baffle member is disposed on the axis in the downstream region spaced from a surface forming the downstream end of the housing, the housing being open between the downstream end and the third baffle member.

17. Apparatus according to claim 16, including a plurality of additional baffle members extending axially from the second baffle member through the first baffle member to the third baffle member, the additional baffle members extending from the conduit in the upstream chamber to the periphery of the housing and from the periphery of the housing in the downstream chamber inwardly a predetermined distance spaced from the axis, the third baffle member extending from the predetermined distance outwardly to the periphery of the housing; the housing thereby being defined by a plurality of upstream regions spaced about the axis of rotation, a centrally located cavity in the downstream chamber, and a plurality of downstream regions in communication with the central region and spaced about the axis of rotation.

18. Apparatus according to claim 17, wherein the periphery of the housing is defined by a cylindrical segment and a conical segment, the segments intersecting adjacent the upstream regions, with the cylindrical segment extending in the direction of the upstream regions and the conical segment extending in the direction of the downstream regions.

19. Apparatus according to claim 18, including a fourth baffle member which is annular and is axially spaced in the upstream direction from the second baffle member, the fourth baffle member extending from the cylindrical segment inwardly to adjacent the conduit.

BAD ORIGINAL

20. Apparatus according to claim 19, including inlet means in communication with the upstream conduit for admitting mixture into the apparatus and outlet means in communication with a passage formed between the second and fourth baffle members for discharging effluent, the outlet means being disposed at a greater vertical height than the inlet means, whereby effluent can be aerated when discharged from the outlet means.

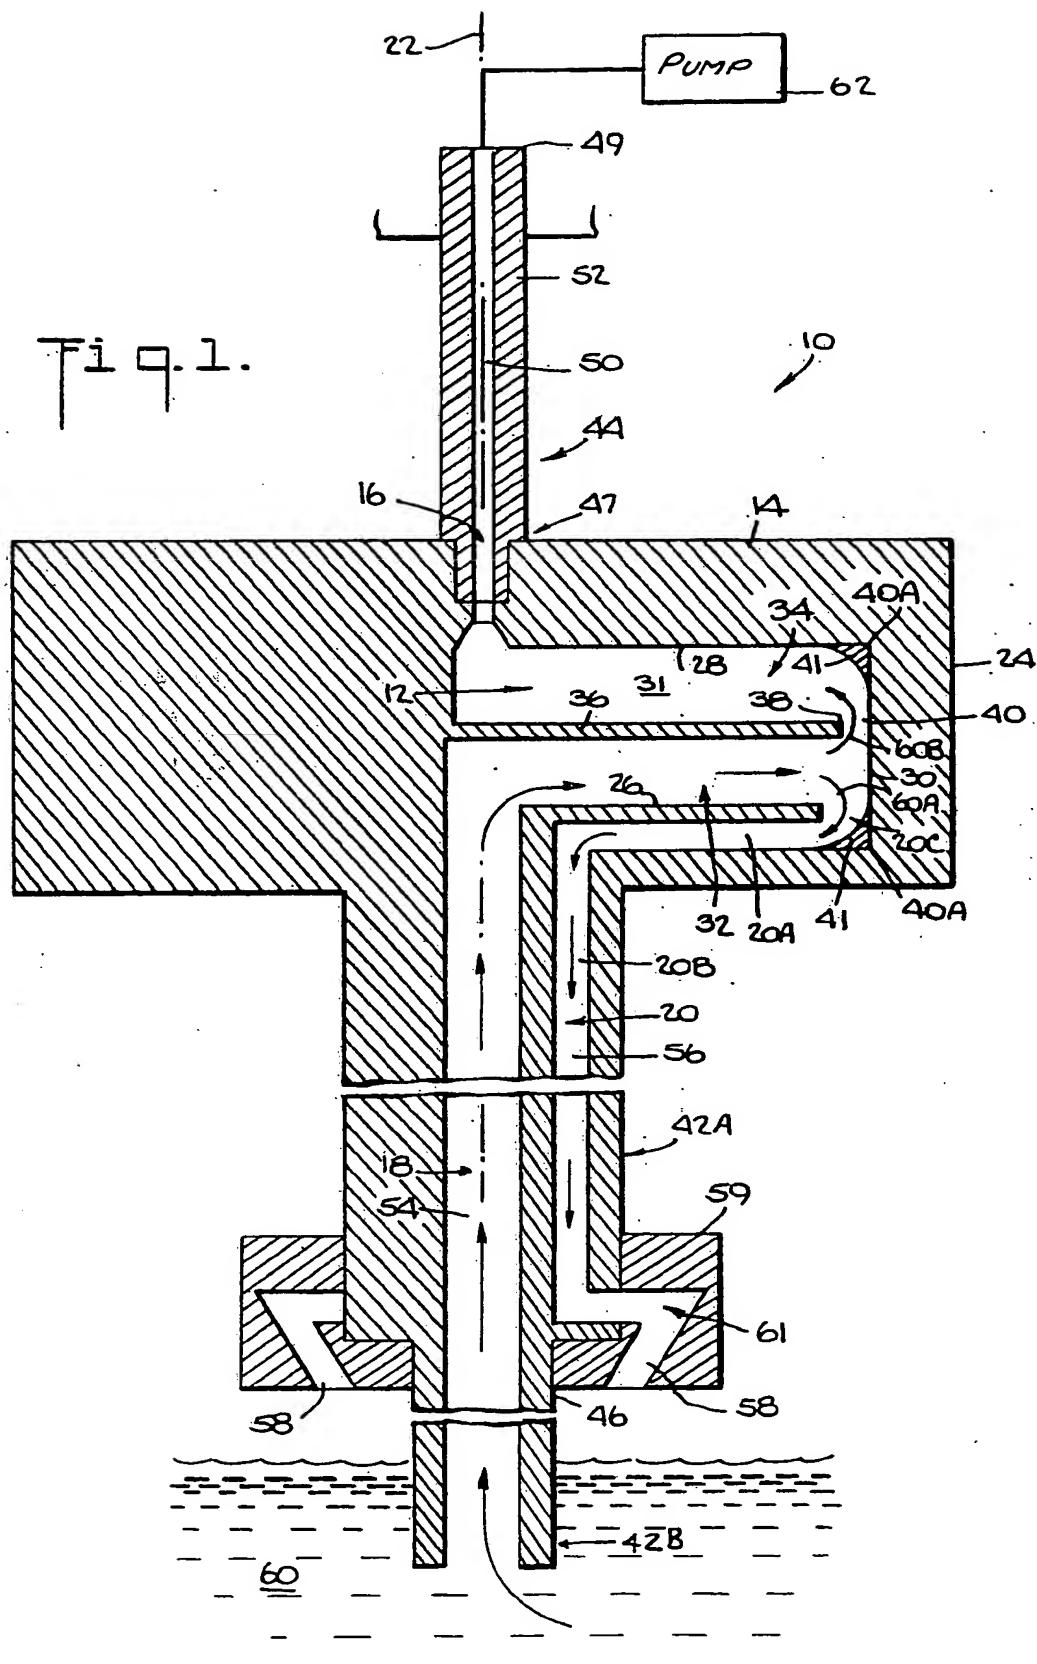

21. A method of separating solids and liquids in a solids-liquid mixture comprising the steps of introducing mixture to be separated into a first chamber, removing a minor part of the mixture into a second rotating chamber having a mass flow and turbulence which are substantially less than those in the first chamber, separating the mixture in the second chamber into solids and liquids and removing the separated solids and liquids from the second rotating chamber.

22. A method according to claim 21, including the step of rotating the first chamber while removing therefrom a minor part of the mixture.

23. A method according to claim 21 or claim 22, wherein the mass flow in the second chamber is maintained below the terminal settling velocity of the solids in the mixture.

24. A method according to any one of claims 21 to 23, wherein shear forces are maintained low in the second chamber while subjecting the mixture therein to centrifugal force resulting from rotation.

25. A method according to any one of claims 21 to 24, wherein the mixture to be separated is subjected to turbulence and centrifugal force in the first chamber and the mixture in the second chamber is subjected to low turbulence and low shear forces while the solids and liquid are separated in the second chamber by centrifugal force.

(54) A method and apparatus for continuously separating solids and liquids in a solids-liquid mixture.

(57) A separation zone (118) for separating solids and liquids from a solids-liquid mixture is provided in which the mixture is subjected to centrifugal force under low shear forces and low turbulence. In the separation zone (118), the flow rate is maintained to be less than the terminal settling velocity of the solids in the mixture. The mixture is introduced into the separation zone (118) from a zone (120) of higher turbulence and higher flow rate than those of the separation zone (118), a minor part of the mixture in the other zone (120) being removed to the separation zone (118). The major part of the mixture is removed from the other zone (120) and discharged through a port (132) and returned to the mixture source in such a manner as to aerate the returned mixture. The separated solids are returned to the mixture source with the major part of the mixture. The separated solids and liquid are removed from the apparatus continuously. The invention is particularly useful in obtaining a highly clarified centrate from sewage sludge.

Equipment for sepn. of suspensions - has truncated conical rotor inside body with attachments to receive sepd. prods., with further extn from fine fractions

CB6-042591

The body (1) contains the rotor (2) and the container (4) for the suspension, with means to receive the sepd. products, and outflow pipes. There is an attachment for the adhesive removal of the particles, with the receiver for the prods. of sepn. being located inside it along the way the material is moving. This attachment is made as drums (8) with external corrugated surfaces. There is also an attachment to ensure a constant level of the suspension, made as a circular trough (5).

USE/ADVANTAGE - To separate materials according to coarseness, density and adhesive properties of the grain surfaces. Can be used in ore-mining, chemical, etc. industries. The sepn. effectiveness is increased by additionally extracting the valuable ingredients from the ultrafine fractions. Bul.35/23.9.85 (3pp Dwg.No 1/1)

EXAMPLE

Into the container (3) the original slurry with 20% of solid phase, is poured. The solid phase consists of tailings from copper-molybdenum factories, with a coarseness of -0.42 to 0mm, contg.

0.0056% Mo and 0.0722% Cu. As the conical rotor (2) turns at a speed of 920 r.p.m. the solid phase is sepd. simultaneously into three prods. with sepn. limits of the particles of 0.126 and 0.028 mm, giving an effectiveness respectively of 91 and 79%. The Mo and Cu content increases by 2.34 times in the coarser class, while in the muds (class 0.028mm) they are reduced by 2.06 times compared with sepn. involving hydro-classification. The sepn. effectiveness (partic. of finely-dispersed fractions) increases with increased cleanliness of the surface of the conical rotor (2), this leading to further increased effectiveness. e.g. of removal of the muds from the materials.
